1 INTRODUCTION
The use of optical motion capture systems to produce high
density motion data in the form of 3D rotational angles in space which demonstrates the
body poses for each frame. In addition to the 3D angles, a set of
Cartesian measurements is also provided, showing the exact
place of the center of the body with respect to the calibration
origin. The overall complete output data is represented by \( A \) as shown in (1) where \( d_i \) represents the location of the \( i \)th axis of the
hip marker in the \( i \)th frame and \( \theta_j \) denotes the rotation of the \( j \)th
marker around the \( x \) axis in the \( j \)th frame. Once both the training
and test samples have been extracted, the database is constructed
as explained in section 3.

\[
A = \begin{bmatrix}
(d_1, d_2, d_3)
& (\theta_1, \theta_2, \theta_3, ..., \theta_i, \theta_j, \theta_k)

M

(d_n, d_m, d_z)
& (\theta_{n1}, \theta_{n2}, \theta_{n3}, ..., \theta_{nj}, \theta_{nk})
\end{bmatrix}
\]

Different captured actions may vary in length (number of frames); therefore a series of time warping manipulations is applied to solve this problem. In simple terms, the signals for each axis of each marker are stretched or shrunk in time to create actions of same duration. Subsequent to the time warping process, two different methods are employed for re-synthesis of motion. The first method is interpolating between existing motions. For instance, interpolation between a high energy walk and a low energy walk results in a medium ranged energy walk. The other technique used is by means of generating a linear transform function between two existing styles of action. The transform function once applied to a new action of same class but different style class, converts the style class of the action.

2 THEORY OF MOTION SYNTHESIS

The output data provided by the motion capture system is in the
form of 3D rotational angles in space which demonstrates the
body poses for each frame. In addition to the 3D angles, a set of
Cartesian measurements is also provided, showing the exact
place of the center of the body with respect to the calibration
origin. The overall complete output data is represented by \( A \) as shown in (1) where \( d_i \) represents the location of the \( i \)th axis of the
hip marker in the \( i \)th frame and \( \theta_j \) denotes the rotation of the \( j \)th
marker around the \( x \) axis in the \( j \)th frame. Once both the training
and test samples have been extracted, the database is constructed
as explained in section 3.

\[
A = \begin{bmatrix}
(d_1, d_2, d_3)
& (\theta_1, \theta_2, \theta_3, ..., \theta_i, \theta_j, \theta_k)

M

(d_n, d_m, d_z)
& (\theta_{n1}, \theta_{n2}, \theta_{n3}, ..., \theta_{nj}, \theta_{nk})
\end{bmatrix}
\]

Different captured actions may vary in length (number of frames); therefore a series of time warping manipulations is applied to solve this problem. In simple terms, the signals for each axis of each marker are stretched or shrunk in time to create actions of same duration. Subsequent to the time warping process, two different methods are employed for re-synthesis of motion. The first method is interpolating between existing motions. For instance, interpolation between a high energy walk and a low energy walk results in a medium ranged energy walk. The other technique used is by means of generating a linear transform function between two existing styles of action. The transform function once applied to a new action of same class but different style class, converts the style class of the action.

3 APPROACH TO DATABASE CREATION
To begin creating a database of animated movements, it was
necessary to determine the types and variations of animations to be included. The animations intended for the motion database include basic animations that are commonly used for in-game animations or simple animation sequences. Examining various
game design documents, default animation sequences for various
game engines, animation tutorials, and articles relating to
personality and behavior provided a basis for our database.
The identified animation types include Walking, Running,
Jumping, Idling, Strafing Left and Right, Crouching, and a
Collapsing or Death sequence. For each animation type, a
secondary list of variation extremes was also identified. These
variations add a level of personality and interest to the basic, unexaggerated animation types. Masculine to Feminine, Old to Young, Tired to Energetic, Happy to Sad, and Determined to Dreamy are these animation variation pairs.

After determining the required animation sequences for the database, each sequence was captured using a six-camera optical motion capture system. A range of varying actors were used in several different motion capture sessions in which each actor performed the animation types in the style of each variation extreme. This collection of raw motion data was later post-processed and used in the motion synthesis process to produce the final database of animation matrices.

4 ANIMATION TOOLKIT

Autodesk Maya is a node-based 3D modeling and animation software suite. Maya provides a scripting language called Maya Embedded Language (MEL) that allows direct access to the wide range of animation tools. This accessibility made Maya (and MEL) an ideal implementation platform for our procedural animation methods.

The toolkit employs a simple Graphical User Interface (GUI) that provides users with a range of animation controls. Organized sequentially, the controls are presented in four steps of our procedural pipeline. Step 1 allows the user to select which existing character set in the scene file, if there is more than one, to apply the new procedural animation. The dropdown menu produces a list of all the existing character sets in the scene graph and choosing an option will select the desired character hierarchy to be animated. Step 2 provides a utility to keyframe each joint for every frame, but can be optional depending on whether these keys already exist for the given character set. Set keys are required in order for new joint rotation values to be retained. Step 3 holds the primary procedures of the animation toolkit. There are two separate dropdown menus that can be used to select the type of animation (walk, run, or jump) and a corresponding animation variation (Masculine to Feminine, Old to Young, or Tired to Energetic). After selecting the two options from the dropdown menu, the user can use the slider control to apply a weight value between the two extremes of the variation. The automatic update button takes the weight percentage of the variation on the right-hand of the slider to the variation on the left-hand of the slider and applies it to the joint rotations character set, producing a new animation. Step 4, provides further control to the user by allowing them to apply any additional manual adjustment values to the newly animated character. The user can apply new rotation values and weighting for a single specific joint (or for all joints) at each individual frame (or all frames) by using the available controls.

In addition to the four primary steps, the user is also presented with visual feedback and animation playback controls. These include visual feedback to the user regarding the current frame being processed and ultimately the total elapsed time for the finished process and the standard Maya playback (Play/Stop, Skip to the End/Beginning and Step Forward/Back a frame). Figure 1 is a screenshot of the Animation Toolkit GUI in its initial startup state.

Using the Animation Toolkit, a user is able to select an animation type and apply a range of variations in order to derive a new animation sequence. As an example, if a user requires a walk sequence with a more masculine distinction, the toolkit is able to facilitate this action. By selecting the Walk type and the “Masculine ↔ Feminine” variation from the two dropdown menus in Step 3, as well as a minimum weight value (i.e. 0.0), the resulting animation is a masculine walk cycle.

However, adjusting the weighting to a maximum value (i.e. 1.0), results in the output of a feminine walk cycle. A user is able to select weight values between the minimum and maximum values that result in a unique mix between the two extremes. Selecting a weight value in the middle (i.e. 0.5) produces neither a masculine or feminine favored walk cycle, but an equal mix between the two variations.

The evaluation of the toolkit involves (1) allowing users (animators) to interact with the GUI and provide feedback and (2) comparing the procedurally generated animation with motion captured ones performing the same actions. Preliminary results show that the toolkit can be successful in creating a range of animated behaviors with an acceptable similarity to motion capture data methods.

Our current procedural method and preliminary tests produce expected animation results. Future extensions to our animation toolkit could include an increase in complexity and number of animation types and variations included in the database to include more uncommon animation types, an expansion of the additional manual controls (to include translation, blending, and other animation options), and translating our existing method from Maya to a designated gaming framework such as Microsoft’s XNA for runtime execution.
